## Preface

This deliverable (D3.4) focuses on the optimization, accuracy assessment, and validation of the phenology models of floral resources (floral resource models) for bees based on field data from Belgium, Portugal, and the UK, and is an output of subtask 3.3.3. Floral resource models describe pollen, nectar, and sugar production levels and their changes throughout the year, and their development was described in detail in Deliverable D3.3. Floral resource models are incorporated into the ALMaSS landscape model representation of landscape elements and crops important to bees across Europe. The floral resource models are of crucial importance for the ApisRAM (honey-bee colony) model being developed under the ALMaSS modelling platform within WP5.

This deliverable consist of the following components:

1) Report, being the present document, in which the methodology and summary of outputs are described;
2) Appendix A: Results of accuracy assessment for flowering phenology [Accuracy_assessment_flowering_phenology.xlsx] - file available in a GitLab Repository (see explanation below);
3) Appendix B: Parameters for final floral phenology models [Flowering_phenology.xlsx] - file available in a GitLab Repository (see explanation below)
4) Appendix C: Validation results [Validation_results.xlsx] - file available in a GitLab Repository (see explanation below).

In addition, we modified the interactive script in Python for the Jupyter Notebook allowing calculation of floral resources available for bees in different habitat units in different years and locations, and generating outputs for the ApisRAM model [Resources_calculator.ipynb] by including results of our optimization procedure. The up-to-date version of the script (and all necessary input files) as well as Appendices A-C are available in a publicly available GitLab repository (https://gitlab.com/ALMaSS/floral resource models).

To contextualise the deliverable described here, the integration of subtask 3.3 .3 within the entire WP3 strategy and in relation to WP5 is first explained in section 1. The short summary of floral resource models, optimization methods applied, and accuracy assessment results are then presented in section 2. Section 3 focuses on the validation of floral resource models and includes a description of field data collection procedures using previously developed field protocols.

## Summary

The main objective of WP3 is to develop a dynamic landscape model across the EU, capturing the major floral resources for bees, considered a key driver of bee health status. Floral resource models developed in task 3.2 allow one to predict the amount of pollen, nectar, and sugar produced by a given bee-friendly species per unit area of a specific landscape element as a function of accumulated growing degree-days. Here, the modified version of the floral resource models described in Deliverable D3.3 is presented. These modifications relate to the modelling of flowering phenology and include adding maximum daily temperature for plant growth and corrections related to altitude and latitude. Furthermore, an optimization procedure for the selection of base and maximum temperatures for growth is applied, together with an accuracy assessment, also for the final models and including corrections related to altitude and latitude. The final models are validated using field data on flowering phenology from Belgium, Portugal, and the UK. The new version of floral resource models is implemented in the Resources_calculator.ipynb script producing outputs for the foraging component of the ApisRAM model.

## 1. Introduction

WP3 "Ecology and environmental drivers" aims to develop a dynamic landscape model, capturing the major floral resources for bees, and to construct landscape suitability maps for honey bees across Europe. To achieve these general aims, this WP is divided into four tasks, with different sub-tasks that have specific aims and links between them, as represented in the WP workflow (Figure 1).

In task 3.1, based on literature information, databases on plant traits and plant-pollinator interactions, beekeeper plant catalogues and bee expert advice (via a questionnaire sent to all B-GOOD members), the most important bee--friendly plant species in different landscape elements across the EU were identified. The list of the bee--friendly species, together with the map and database of the major landscape elements at the EU level (Deliverable D3.1), served as input for task 3.2, and as a platform to construct the landscape suitability maps in sub-task 3.4.2.

The primary aim of task 3.2 was the construction of the phenology models for the most relevant bee-friendly species across Europe. To complete this task, we first generated a database of the floral resources (Deliverable D3.2), including bee-friendly species, considering both crops and wild plants. For each plant species, information on the amount of pollen, nectar and sugar produced, the number of flowers per unit area, single flower lifetime, and flowering start, peak, and end dates were all compiled in sub-task 3.2.1. The databases of major landscape elements with bee-friendly species (Deliverable D3.1) and of flower resources (Deliverable D3.2) were used in sub-task 3.2.2 to develop the floral resource models that were incorporated within the ALMaSS modelling framework to serve the ApisRAM model (WP5; Deliverable D5.1), and other pollinator (mason bee and bumblebee) models being currently under development in other projects.

Task 3.3 focuses on validation of floral resource models based on field data and the generation of spatio-temporal dynamic landscape models for study areas in Belgium, Portugal, and the UK to be able to test the performance of the ApisRAM model. The first-stage integration of floral resource models was applied using spatio-temporal dynamic landscape models for study areas in Belgium and the UK (WP5; Deliverable D5.1). Further tests are planned for study areas in Portugal. The field studies to support validation of floral resource models were performed in Belgium, Portugal, and the UK following specific field protocols developed by the WP3 team (Milestone M15). The field studies included assessment of the composition of plant communities (coverage and abundance of main species within communities), and flowering phenology observations. The field data on plant communities wasere not used as typical validation data. However, they were of crucial importance and serve as: (1) input data to floral resource models for habitat types not described in the EUNIS database, but important from the point of view of pollinators (e.g., urban parks); and (2) a source of verification for major bee-friendly species reported for the habitat types from the EUNIS database. The field data on flowering phenology was used for validation of phenology models, which are described in this deliverable. The validated floral resource models will be updated within the ALMaSS platform to run together with the ApisRAM model (second-stage integration; subtask 3.4.1).

In sub-task 3.4.2, the main goal is to build landscape suitability maps using geospatial data sources at the pan-European scale, namely land cover maps (from task 3.1), plant species distribution, weather data, digital elevation models, topographic data, and remote sensing to construct detailed spatio-temporal dynamic landscape maps at the EU scale. Combining this geospatial information with nutritional values from the database of floral resources (sub-task 3.2.1) and phenology models (sub-task 3.2.2) will provide spatio-temporal information about the main resources available for bees across the EU.

Figure 1: Diagram of the workflow of the work package 3, showing the major links between tasks and sub-tasks.

## 2. Optimization and accuracy assessment of flowering phenology models

The floral resource models (Deliverable D3.3) describe pollen, nectar, and sugar production levels as a function of growing degree-days (GDD) (i.e., degree days above the base temperature $\mathrm{T}_{\mathrm{b}}$, a temperature threshold below which plant development stops) in various landscape elements and crops important to bees across Europe. The models integrate information on plant composition in different habitat units (Deliverable D3.1) with nectar and pollen production (Deliverable D3.2), and flowering phenology. In the first version of floral resource models, the timing of flowering was related only to temperature. This means that onset, peak and end of flowering were determined based on accumulated GDD. For calculation of daily GDD the following formula was applied:

Daily GDD $\left({ }^{\circ} \mathrm{C}\right)=\left(\left(\right.\right.$ Daily Max $T{ }^{\circ} \mathrm{C}+$ Daily Min $\left.\left.T{ }^{\circ} \mathrm{C}\right) / 2\right)-T_{b}{ }^{\circ} \mathrm{C}$
For all wild plant species, GDD were accumulated starting from $1^{\text {st }}$ January and using the base temperature ( $\mathrm{T}_{\mathrm{b}}$ ) of $4^{\circ} \mathrm{C}$. For crops we used crop-specific base temperatures, determined from the literature (see Deliverable D3.3, Table 1). For permanent crops (i.e., fruits, olives), GDD were accumulated starting from $1^{\text {st }}$ January while for annual crops it was accumulated starting from the sowing date.

Here we described the updated version of floral resource models, in which calculation of GDD was modified by adding the maximum temperature for growth, above which plant growth is inhibited. In addition, optimization procedures were applied to select the base and maximum temperatures giving the best fitted flowering phenology models according to the root-meansquare error (RMSE). Lastly, corrections related to altitude and latitude were included, and accuracy assessment of the final models performed.

### 2.1. Input data for modelling of flowering phenology

The following data sources were integrated in the database on floral phenology:

[^0]and data on peak of flowering of corn), fruit crops (including data on start, peak and end of flowering of apple, pear, cherry, morello, and plum; and data on start of flowering of apricot, peach, and different kinds of berries), and vine (including data on start, peak and end of flowering of early, middle-late and late ripeness varieties).
These data are referred to as 'DWD'-data and tables containing these data are named with the prefix 'DWD'.

- The database on nectar and pollen production (Deliverable 3.2).

These data are referred to as 'UJ'-data and tables containing these data are named with the prefix 'UJ'.

- Phenological observations of development stages of selected crops (including data on start and end of flowering of winter oilseed rape) collected by the Polish Official Variety Testing (COBORU) in years 2007-2016.
These data are referred to as 'COBORU'-data and tables containing these data are named with the prefix 'COBORU'.
- Phenological observations from the multitaxon database on phenology from the Russian Federation, Ukraine, Uzbekistan, Belarus and Kyrgyzstan (Ovaskainen et al. 2020).

The data cover the period 1890-2018, with $96 \%$ of the data being from 1960 onwards. The database is rich in plants, birds and climatic events, but also includes insects, amphibians, reptiles and fungi. The database was restricted to plant flowering phenology observations within the spatial and temporal coverage of the E-OBS meteorological data.
These data are referred to as 'CNC'-data and tables containing these data are named with the prefix 'CNC'.

Flowering phenological observations collected by Jachuła et al. (2021) for bee-friendly species.
These data are referred to as 'JJ'-data and tables containing these data are named with the prefix 'JJ'.

The current version of flowering phenology database (available in the GitLab repository) includes 8223641 records, 7195055 ( $87.5 \%$ ) of which refer to onset of flowering.

### 2.2. Optimization and accuracy assessment of flowering phenology models

### 2.2.1. Optimization of the base temperature

Optimization of base temperature was done based on 7195055 records on the onset of flowering. First, for each record, the day of the year indicating onset of flowering was converted to GDD based on meteorological data from the E-OBS database using a range of base temperatures between 0 and 9 Celsius degrees (range of base temperatures was selected based on literature review). Next, mean GDD needed for onset of flowering were calculated for each species and base temperature being tested. These mean GDD values were used to predict the onset of flowering (as day of the year) for each plant phenological record being analysed. The predicted and actual values for each record were compared using RMSE, and the minimum RMSEs were reported for each species (Appendix A). Summary of the results indicating RMSEs for plant families, and for all records are provided in Table 1.

Zero degrees Celsius was the best performing base temperature (i.e., in terms of minimalizing RMSE) for most of the species (Figure 2), plant families as well as when considering all
records together (Table 1). This temperature was therefore applied when generating floral resource curves for ALMaSS to be used in the ApisRAM model.

Table 1. Summary of the accuracy assessment for the onset of flowering (RMSE values). Different base temperatures between 0 and 9 degrees Celsius were tested. Lowest RMSE values for each family, belonging to the most accurate base temperature for that family, are marked in green. If number of observations for a given species was $<3$, RMSEs were not calculated and base temperature of 0 degrees Celsius was assumed.

Figure 2. Frequency distribution for the best fitted base temperature for onset of flowering.

### 2.2.2. Optimization of the maximum temperature

Optimization of the maximum temperature for growth was done based on 320974 records of the end of flowering. First, for each record, day of the year indicating the end of flowering was converted to GDD based on meteorological data from the E-OBS database using a range of maximum temperatures between 15 and 33 degrees Celsius. Next, the mean GDD needed for the end of flowering was calculated for each species and maximum temperature being tested. These mean GDD values were used to predict the end of flowering (as day of the year) for each plant phenological record being analysed. The predicted and actual values for each record were compared using RMSE, and the minimum RMSEs were reported for each species (Appendix A). A summary of the results indicating RMSEs for plant families and for all records is provided in Table 2.

28 degrees Celsius was the best performing maximum temperature (i.e., in terms of minimalizing RMSE) for most of the species (Figure 3), plant families as well as all records (Table 2). This temperature was therefore applied when generating floral resource curves for ALMaSS to be used in the ApisRAM model.

Table 2. Summary of the accuracy assessment for the end of flowering (RMSE values). Different maximum temperatures between 15 and 33 degrees Celsius were tested but here results for temperatures between 18 and 30 degrees Celsius are shown. Lowest RMSE values for each family are marked in green. If number of observations for a given species was $<3$, RMSEs were not calculated and max temperature of 28 Celsius degrees was assumed.

| Plant family | No of records | Maximum temperature |  |  |  |  |  |  |  |  |  |  |  |  |

Figure 3. Frequency distribution for the best fitting maximum temperature for end of flowering.

### 2.2.3. Corrections for altitude and longitude

Flowering patterns can vary within plant species with changing abiotic conditions. In particular, it has been shown that the start of flowering is delayed with increasing elevation (e.g., Bucher et al. 2017; Bucher and Römermann 2020). Populations at higher elevations need less temperature accumulation to start flowering than populations of the same species at lower elevations, but the magnitude of this responses is very species dependent. Also, latitude can influence onset of flowering, which relates to photoperiod (e.g., Cho et al., 2017; White 1995).

Here, GDD for onset of flowering (calculated for base temperature of 0 degrees Celsius and max temperature of 28 degrees Celsius) were analysed against latitude and altitude at the plant family level. Although it was indicated in the literature that the magnitude of a response may be species-specific, we decided to apply correction at the family level as not enough data were available for most of the species to perform correction at the species level. Therefore, for each plant family with more than 10 records on the onset of flowering, based on data preprocessing a second order quadratic surface was fitted using least-squares solution in the SciPy Linear Algebra package in Python 3.7 was applied:

GDD for onset of flowering $=C[4]$ * $A L T^{2} .+C[5]$ * LAT $^{2} .+C[3]$ * ALT * LAT + C[1] * ALT + C[2] * LAT + C[0]
where $\mathrm{C}[0[$ to $\mathrm{C}[5]$ are parameters of the quadratic model; ALT and LAT stand for altitude (in meters above sea level) and latitude (in decimal degrees)

For plant families with less than 10 records on onset of flowering, a general surface fitted to all data on onset of flowering was applied. Parameters for fitted surfaces are presented in Table 3, while Figure 4 shows examples of best-fitted surfaces for Colchicaceae and Leguminosae families.

For each record on flowering, a correction for altitude and longitude was then applied as follows. Mean GDD at average altitude and latitude values for a plant family (given by the fitted surface) were compared to the modelled species mean GDD value (see Appendix B), predicting the onset of flowering at a specific altitude and latitude for a given record and the resulting difference was applied as a correction value to that respective record.

Corrected mean GDD values were used to predict the onset of flowering (as day of the year) for each plant phenological record being analysed. The predicted and actual values for each record were compared using RMSE, and the minimum RMSEs were reported for each species (Appendix A). The RMSEs for models with and without the corrections for altitude and longitude were then compared for all species (Appendix A). A summary of the results indicating RMSEs for plant families, and for all records is provided in Table 4.

In general, application of a correction for altitude and longitude slightly lowered the resulting RMSE values (Table 4), suggesting greater accuracy in the models. However, we also found that for some species (e.g., Alnus incana, Anemone hepatica, Primula veris, Thymus vulgaris; Appendix A) the corrected flowering phenology models gave much higher RMSEs, which are also reflected in the results from their respective families (Table 4).

Table 3. Parameters for best-fitted second-order quadratic surfaces to the data on the onset of flowering at the family level.

A)

B)

Figure 4. Predicted flowering phenology and its variation with altitude and latitude. Exemplary best-fitted surfaces for (A) Colchicaceae; (B) Leguminosae families. The red dots show GDD values for the onset of flowering plotted against the altitude (ALT) in meters above sea level and latitude (LAT) in decimal degrees.

Table 4. Comparison of the RMSEs for the onset of flowering with and without corrections for altitude and latitude (calculated using a base temperature of 0 degrees Celsius and maximum temperature of 28 degrees Celsius). If number of observations for a given species was < 3, RMSEs were not calculated.

### 2.3. Field data

### 2.3.1. Field data collection

The primary goal of field data collection was to gather data that could be used for the validation of floral resources maps and models developed across the various tasks within WP3, and also and to fill specific information gaps during the development of the phenological model. The field-work was conducted in three countries (Portugal, Belgium and United Kingdom) using three field protocols developed under B-GOOD and described in Milestone MS15.

These protocols are part of Tasks 3.1 and 3.3 and serve various purposes. The primary goal of Field Protocol 1: "Assessment of plant species composition on key landscape elements/habitats important for bees" was to determine the species composition in selected key plant communities (i.e. landscape elements or habitats) important for bees. Field Protocol 1 was used to determine the plant species composition of specific ALMaSS landscape elements and to confirm/validate the plant composition of some BIOEUNIS habitat types, developed in Task 3.1. The main goal of Field Protocol 2: "Assessment of Phenology of Floral Resources for Bees" was to determine the flower phenology of targeted plant species to construct flowering phenological curves for targeted plant species. Field Protocol 2 was used to validate the floral resource models developed in Task 3.2 (see Section 2.4). The primary goal of Field Protocol 3: "Floral resources evaluation (detailed method)" was to conduct a detailed evaluation of the floral resources in each landscape window with B-GOOD miniapiaries to map resource availability. Field protocol 3 was divided into two parts: Part 1 "Assessment and quantification of floral resources", aiming to determine the species composition, species cover, and flower abundance, and Part 2 -"Flowering species characterization", aiming to quantify the number of flowers per individual plant, and the nectar and pollen production of target plant species. Field Protocol 3 was also used to make a detailed assessment of plant species composition and plant resources at the landscape level, as well as to fill the gaps in knowledge about pollen and nectar production of some target plant species.

Field protocols have been implemented in Portugal, the United Kingdom, and Belgium. Field protocols 2 and 3 were fully implemented at the three countries. However, field protocol 1 was not implemented as a stand-alone field protocol in Portugal and the United Kingdom due to logistic and time constrains primarily caused by the COVID pandemic. However, this does not hamper our ability to obtain landscape-specific plant composition data, because the information gathered in this protocol can be derived entirely from the implementation of the first part of Field Protocol 3. As a result, for Portugal and the United Kingdom, Field Protocol 1 data were derived from the first part of Field Protocol 3. The full dataset gathered by the implementation of these three protocols is upload and available in the B-GOOD data portal (https://beehealthdata.org/datasets/1642b97c-e81e-4fad-b1bd-34c6d4900f99).

As explained above, the field data collected by the implementations of the field protocols could be categorized into three main groups: Plant Species Composition (Field Protocol 1 and Field Protocol 3: Part 1), Phenology of Floral Resources (Field Protocol 2), and Flowering Species Characterization (Field Protocol 3: Part 2). A general overview of data collected from each of these groups is presented below.

### 2.3.2. Plant Species Composition

One crucial point in the evaluation of the floral resources is determining the species composition and cover of "bee-friendly" plant species present in key landscape elements or habitats important for bees

The information about the species composition was used to derive the plant species composition of specific landscape elements in ALMaSS (e.g. roadside verge, field margins), where no information about the species composition existed from BIOEUNIS habitats due to the small scale of these elements. The plant species composition of different landscape elements and habitat types was assessed using the field data obtained from the implementation of field protocol 1 (Belgium) and field protocol 3: part 1 (Portugal and the UK). Additionally, this information may be used to confirm/validate the plant species composition of some BIOEUNIS habitats.

The main plant species composition for the selected habitats of each of the three countries is presented in Figure 5. As expected, there is evidently a clear separation between habitat types within each country and, by association, differences in plant species composition.

Figure 5. Multivariate ordination (PCA) of the species composition in the surveyed plant communities of Portugal, Belgium, and the United Kingdom. Arrows represent the different plant species, and squares represent the plant communities. Left panels show Axis 1 and 2 and right panels shows Axis 1 and 3 of the PCA. The plant species label is composed of the first four letters of the genus and four letters of the specific epithet. For simplification of the diagrams, only species having a contribution higher than $15 \%$ are represented.

### 2.3.3. Phenology of Floral Resources

Information about the phenology of floral resources, namely bee-friendly plant species, is fundamental to understand the availability of resources for bees over time. Together with the information about the plant species composition, abundance, and coverage, flowering phenology (particularly of those bee-friendly species) allows to determine the floral resources available for bees across both space and time.

The information on the phenology of the floral resources was used to validate the updated flowering phenology models (see Section 2.4.) and was obtained by the implementation of the Field Protocol 2 for previously selected target plant species. In total, there were 94 plant species surveyed in the three countries: 40 species in Portugal, 20 in Belgium and 34 in the United Kingdom. A full list of surveyed plant species by country can be found in Table 5.

Table 5. List of plant species monitored for flowering phenology in Portugal, Belgium, and the United Kingdom.

| Country | Species |  |
| :---: | :---: | :---: |
| Portugal | Arbutus unedo | Erica umbellata |
| Portugal | Calluna vulgaris | Eucalyptus globulus |
| Portugal | Carduus tenuiflorus | Galactites tomentosus |
| Portugal | Carlina hispanica | Genista tridentata |
| Portugal | Castanea sativa | Hypericum perforatum |
| Portugal | Chamaemelum sp. | Jasione montana |
| Portugal | Cirsium vulgare | Lavandula pedunculata |
| Portugal | Cistus crispus | Lavandula stoechas |
| Portugal | Cistus ladanifer | Lavatera cretica |
| Portugal | Cistus monspeliensis | Lithodora prostrata |
| Portugal | Cistus salviifolius | Rosmarinus officinalis |
| Portugal | Crataegus monogyna | Rubus ulmifolius |
| Portugal | Cytisus multiflorus | Salix sp. |
| Portugal | Cytisus striatus | Silybum marianum |
| Portugal | Digitalis purpurea | Trifolium campestre |
| Portugal | Echium plantagineum | Trifolium repens |
| Portugal | Echium tuberculatum | Ulex europaeus |
| Portugal | Erica arborea | Ulex micranthus |
| Portugal | Erica australis | Ulex minor |
| Portugal | Erica cinerea | Ulex sp. |
| Belgium | Acer campestre | Prunus serotina |
| Belgium | Acer pseudoplatanus | Prunus spinosa |
| Belgium | Alnus glutinosa | Robinia pseudoacacia |
| Belgium | Castanea sativa | Rubus sp. |
| Belgium | Cirsium arvense | Salix alba |
| Belgium | Corylus avellana | Salix caprea |
| Belgium | Crataegus monogyna | Taraxacum officinale |
| Belgium | Frangula alnus | Tilia platyphyllos |
| Belgium | Hedera helix | Trifolium pratense |

| Country | Species |  |
| :--- | :--- | :--- |
| Belgium | Prunus avium | Vicia cracca |
| United Kingdom | Camellia sp. | Hyancinthoides non-scripta |
| United Kingdom | Quercus robur | Ilex sp. |
| United Kingdom | Acer sp. | Impatiens glandulifera |
| United Kingdom | Achillea millefolium | Ligustrum sp. |
| United Kingdom | Bellis sp. | Lotus cornicalatus |
| United Kingdom | Borago officinalis | Malus domestica |
| United Kingdom | Brassica napus | Myosotis arvensis |
| United Kingdom | Buddleia variabilis | Prunus avium |
| United Kingdom | Castanea sativa | Rubus fruticosus |
| United Kingdom | Centaurea nigra | Salix sp. |
| United Kingdom | Cirsium | Senecio jacobaeae |
| United Kingdom | Citrus aurantifolia | Sorbus sp. |
| United Kingdom | Clematis sp. | Taraxacum sp. |
| United Kingdom | Crataegus monogyna | Trifolium pratense |
| United Kingdom | Epilobium sp. | Ulex europaeus |
| United Kingdom | Filipendula ulmaria | Viburnum sp. |
| United Kingdom | Hedera helix | Vicia sp. |

A general overview of the floral resources available for bees across the year for each country is presented in Figure 6 (due to the high number of species surveyed, for graphical simplicity purposes, instead of plotting the average percentage of flowers per species, a GAM technique was adopted as a way to visualise the flowering peaks in each country across time, without an aim to make any type of prediction).
It is evident that the flower resources available for bees vary from country to country with a bimodal distribution in Portugal (peaks in spring and autumn) and unimodal distributions in Belgium (peak in spring) and the UK (peak during summer). Resource availability for bees reflects a country's plant species composition and also the result of different environmental factors (e.g. rain, temperature, light).

Figure 6. Mean percentage of flowering predicted from a generalized additive model (GAM) of the surveyed plant species in Portugal, Belgium, and the United Kingdom. The grey area represented the $95 \%$ confidence intervals of the predicted value.

### 2.3.4. Flowering Species Characterization

Information about the amount of nectar and pollen available in flowers of each bee-friendly species is essential to quantify the amount of food the floral resources can provide for bees.

Part of the information about the pollen and nectar already exists for some species in the literature and was compiled in Deliverable D 3.2 (Database on Nectar \& Pollen Production). However, for several plant species, information is non-existent. For that purpose, for target plant species where information about pollen and nectar was missing or is unreliable, the pollen and nectar contents were measured with the objective of filling these gaps by implementing part 2 of Field Protocol 3.

The main results of the quantification of the pollen and nectar of the selected target species are presented in Table 6. The target plant species selected among the countries is very diverse, with species of different habits/life forms (i.e., trees, shrubs and herbs). It is also evident for some of the same plant species measured in different countries (e.g. Trifolium, Taraxacum, Rubus), that the quantity of pollen and nectar exhibit high natural variation, probably due to environmental factors.

Table 6. Flowering characterization of the target plant species in Portugal, Belgium, and the United Kingdom.

| Country | Species | No. of Anther s/ flower | No. Of pollen grains / anther | No. Of pollen / flower | No. Of pollen / inflores cence | No. of flowers per flower cluster / catkin | Nectar volume / flower ( $\mu \mathrm{l}$ ) | Sugar concen tration / flower (\% Brix) | Sugar concen tration / flower ( $\mu \mathrm{g}$ ) |

### 2.4. Validation of flowering phenology models with field data

Validation of flowering phenology models was performed based on field data gathered in Belgium, Portugal and the UK (see section 2.3.3). For Belgium it was possible to validate flowering phenology models for all 20 species investigated in the field. In case of the UK, some assumptions regarding species had to be applied as some records had only information at the genus level (e.g., all records reported for Acer sp. were assumed to represent Acer campestre and all records reported for Ilexsp. were assumed to represent Ilex aquaifolium; see Appendix C). These assumptions were based on species distribution maps from the Online Atlas of the British and Irish Flora (https://plantatlas.brc.ac.uk/). As the Clematis genus is very broad and flowering time differs considerably between species from this genus, we decided to not include these records in the validation process. In a nutshell, it was possible to validate flowering phenology models for 33 of 34 species investigated in the field. Although the number of species for which flowering phenology was investigated in Portugal was the highest among all three countries ( $\mathrm{N}=40$ ), it was possible to validate flowering phenology models for only 12 of them. The rest of the species had no flowering phenology models due to no records available in the current version of the flowering database. To overcome this aspect, it is planned to increase the phenological database with phenological data for southern European species using data gathered from the Portuguese Flora-on project (https://flora-on.pt/).
For each of the records gathered in the field we predicted the flowering period based on the species name, year of observation and information about latitude, longitude and altitude according to our optimized flowering phenology models (with base temperature of 0 degrees Celsius and maximum temperature of 28 degrees Celsius) corrected and un-corrected for altitude and latitude. We then assessed if the flowering period observed in the field remained within the range predicted by the flowering phenology model (mean GDD +/- SD; Appendix C).

In general, we were able to predict the onset of flowering much better than the end of flowering. Flowering phenology models corrected for altitude and longitude predicted better the end of flowering but were less able to predict the start of flowering (Figure 7).

Figure 7. Results of validation of flowering phenology models with field data. Numbers indicated number of observations correctly or un-correctly predicted within the range of flowering period (mean GDD +/- SD) by the optimized flowering phenology models (with base temperature of 0 degrees Celsius and maximum temperature of 28 degrees Celsius) corrected (A) and un-corrected (B) for altitude and latitude.

### 2.5. Important remarks and discussion of the results

The floral resource models can be considered 'living' models and are designed in such a way that they can be easily updated when more/additional data on pollen, nectar or sugar production, phenology of bee-friendly species or plant species composition in landscape elements important for bees, are made available. It is the intention that any new data be added to the database during and also after the project finishes.

The accuracy assessment and validation of flowering phenology provided in this deliverable are based on the current version of the flowering database. The next step includes generating the flowering phenology models for important southern European 'bee-friendly' species for which no records are available in the phenology database. This will be done based on data
from the Flora-On (https://flora-on.pt/) portal coordinated by the Portuguese Botanical Society. That, however, requires applying a special methodology to deal with more general data on flowering phenology, as most of flowering records gathered in the Flora-On portal have no information of flowering stage. This new methodology will allow one to use the rest of field data on phenology of floral resources gathered in Portugal in the validation process.

The correction for altitude and longitude applied to the flowering resource models was based on the surfaces generated at the plant family level, which for some species did not improve the models' accuracy. It seems that for same families / species the number of observations was too low to generate the well fitted models. We plan to further investigate the dependence of flowering on altitude and latitude at the species level.

The validation of the flowering resource models based on gathered field data showed that, although we are good in predicting the onset of flowering, the end of flowering is rather poorly predicted to be too early than observed. The poorer prediction of end of flowering compared to onset of flowering could be related to the number of records based on which this stages of flowering are being modelled ( 320974 records on the end of flowering compared to 7195055 records on the onset of flowering). The other reason may be related to the fact that most of the flowering records in the phenology database come from the Continental pedo-climatic zone while validation was performed in the Atlantic and Mediterranean zones. We are therefore in the process of generating separate flowering resource models for each pedoclimatic zone to see if that improves accuracy assessment and validation results.

## 3. List of appendices

Appendix A: Results of accuracy assessment for flowering phenology
[Accuracy_assessment_flowering_phenology.x|sx]
Appendix B: Parameters for final floral phenology models [Flowering_phenology.xlsx]
Appendix C: Validation results [Validation_results.xlsx]
Appendices are available in a GitLab Repository:
(https://gitlab.com/ALMaSS/floral resource models).
